## 23 **Abstract**

24           The feet of ground-dwelling birds retain many features of their dinosaurian ancestry.  
25 Experiments with living species offer insights into the complex interplay among anatomy,  
26 kinematics, and substrate during the formation of Mesozoic footprints. However, a key aspect of  
27 the track-making process, sub-surface foot movement, is hindered by substrate opacity. Here, we  
28 use biplanar X-rays to image guineafowl walking through radiolucent substrates of different  
29 consistency (solid, dry granular, firm to semi-liquid muds). Despite substantial kinematic  
30 variation, the foot consistently moves in a looping pattern below ground. As the foot sinks and  
31 then withdraws, the claws of the three main toes create entry and exit paths in different locations.  
32 Sampling these paths at incremental horizons captures 2-D features just as fossil tracks do,  
33 allowing depth-based zones to be characterized by the presence and relative position of digit  
34 impressions. Examination of deep, penetrative tracks from the Early Jurassic confirms that  
35 bipeds had an equivalent looping response to soft substrates ~200 million years ago. Our  
36 integration of extant and extinct evidence demonstrates the influence of substrate properties on  
37 sinking depth and sub-surface foot motion, both of which are significant sources of track  
38 variation in the fossil record of dinosaurs.

39

## 40 **1. Introduction**

41           Fossil dinosaur tracks preserve unique evidence of locomotion in long-extinct species [1-  
42 4]. Rather than being perfect molds of static feet, track morphologies arise through the dynamic  
43 interplay of pedal anatomy, step kinematics, and substrate properties [5-10]. Ground-dwelling  
44 birds have proven to be excellent models for experimentally studying these interactions [11-19].  
45 The functionally three-toed feet of many species closely resemble those of bipedal, non-avian

46 dinosaurs [20-21], allowing the visible movements responsible for shallow tracks to be studied  
47 directly.

48         With each step, a dinosaur deformed not only the exposed air-sediment boundary, but a  
49 volume of substrate beneath [7,17,22-25]. Layered sediments, once lithified, can develop planes  
50 of weakness at multiple potential track surfaces below the originally exposed horizon  
51 [7,17,22,26-28]. In species with relatively narrow toes (theropods and small ornithopods),  
52 compliant substrates can flow around and over the foot, leaving only furrow-like seams marking  
53 its deep passage [14,27-32]. Such ‘penetrative tracks’ offer an excellent source of functional  
54 information [14,33-36], capturing foot movements throughout the track volume. Yet tracks on  
55 bedding planes sampled from within these depths can differ substantially [17,34,37-38], both  
56 from each other and from the foot that made them.

57         Herein, we quantify the three-dimensional (3-D) foot movements of a chicken-like bird  
58 (guineafowl) walking through a spectrum of deformable substrates. Following earlier studies of  
59 burrowing [39-45] and stepping [17,46-48], we use X-ray imaging to see through opaque ground.  
60 We emulate potential fossil track surfaces within each track volume by sampling guineafowl  
61 movement data at depth intervals, thereby identifying common patterns among the highly  
62 variable toe trajectories. Using this new perspective, we re-examine morphological variation  
63 among the classic Early Jurassic tracks of the Connecticut Valley [37-38,49-57] and discern  
64 previously unrecognized similarities with modern birds.

65

## 66 **2. Material and Methods**

67 *(a) Animals, substrates, and recording*

68           Biplanar X-ray data were collected from three adult Helmeted Guineafowl (*Numida*  
69 *meleagris*). All live animal experiments were conducted in accordance with the Institutional  
70 Animal Care and Use Committee of Brown University.

71           Dry and cohesive substrates were contained in a plastic trough filled to a depth of ~18 cm  
72 to form a trackway, which was enclosed by a clear acrylic tunnel. In lieu of sand, we used poppy  
73 seeds (*Papaver somniferum*) [17,58]. Artificial mud [10] was mixed from ~60  $\mu$ m glass bubbles,  
74 ball clay, and water. Mud consistency was adjusted from very firm to semi-liquid by evaporating  
75 or adding water. For comparison, birds also walked across a stiff, non-deformable trackway.

76           Walking guinea fowl were recorded at 250 fps by two X-ray and two standard light  
77 cameras (Fig. 1a, b), along with images for camera calibration and X-ray undistortion. One bird  
78 had ~2 mm disc-shaped lead markers fixed with cyanoacrylate beneath each claw (Fig. 1b).

79

#### 80 *(b) Point tracking, animation, and depth sampling*

81           3-D toe coordinates for the marked individual were extracted in XMALab [59-60]. and  
82 animated in Maya 2020 (Autodesk Inc., San Rafael, CA, USA). For the unmarked birds, point  
83 rotoscoping [47] was done in Maya using virtual camera calibrations and undistorted video from  
84 XMALab. 58 trials of birds walking on deformable substrates were analyzed, yielding 81  
85 subsurface steps (Table 1). CT-based bone models were animated for several trials using a  
86 combination of marker-based X-ray Reconstruction of Moving Morphology [61] and Scientific  
87 Rotoscoping [59].

individual	tracking method	number of trials analyzed				number of complete steps analyzed			
		solid	dry granular	muds	total	solid	dry granular	muds	total
6	rotoscopy	6	2	16	24	10	4	22	36
7	marker-based	5	12	17	34	8	16	23	47
8	rotoscopy	5	11	0	16	8	16	0	24
		16	25	33	74	26	36	45	107

88

89 **Table 1.** Overview of analyzed guineafowl data.

90

91 The paths of the three main toes (II-IV) were visualized in Maya by connecting their claw  
92 locations at each frame into motion trails (Fig. 1c). Substrate contact for digit III was identified  
93 from standard video, thereby setting the initial height of the substrate surface. To sample sub-  
94 surface motion trails in the vertical dimension (equivalent to bedding planes spanning the track  
95 volume), we extracted the coordinates at which each claw passed down (entry) or up (exit)  
96 through depth horizons set at 5 mm increments. At each increment, the 2-D horizontal position  
97 of the claws were used to calculate three variables: ‘digit III offset,’ defined as the difference in  
98 entry and exit of the middle toe, measured along the direction of travel; ‘digit II-IV width,’  
99 measured as the distance between the side toes, for both entry and exit pairs; and, “digit  
100 representation,” simply the presence or absence of each toe at each increment. Sample horizons  
101 and variable graphs were plotted in R [62].

102

103 *(e) Fossil specimens*

104 All fossil specimens included in this study are housed in the Beneski Museum of Natural  
105 History at Amherst College, Amherst, MA, USA and designated ACM-ICH.

108

## 109 **2. Results**

### 110 *(a) Guineafowl sub-surface foot kinematics*

111 Across trials, guineafowl slowed down, sped up, and paused frequently. Such non-steady  
112 locomotion provided a broad sampling of kinematic variation from the three individuals. Normal  
113 striding steps were by far the most common, although a few trials included non-alternation.

114 Guineafowl sank to a wide range of depths (1.15 – 13.13 cm), penetrating deepest in semi-liquid  
115 muds.

116 As characterized by the paths of the three main toes, sinking and withdrawal exhibited  
117 consistent patterns. A lateral view of digit III, which forms the central axis of the tridactyl foot, is  
118 exemplary. Unlike its V-shaped path above solid surfaces, digit III always followed a loop below  
119 ground (Fig. 1d). Plotting digit III offset (Fig. 1e) reveals a consistent relationship between entry  
120 and exit, despite step by step variation in angle of entry, specific loop shape, and maximum  
121 depth. Digit III's arc-like withdrawal typically crossed from behind entry (negative) to in front of  
122 entry (positive) prior to removal. As the foot sank, digits II and IV remained widely spread until  
123 they reached their maximum depth. Upon withdrawal, the side toes collapsed towards digit III  
124 throughout their arcing ascent (Fig. 1f, g). The combination of anterior-posterior looping and  
125 transverse collapse indicates that the three main claws crossed through all horizons above their  
126 maximum depth twice, but in different locations (Fig. 1h). Such dissimilar entry and exit paths  
127 were found on all deformable substrates.

128

### 129 *(b) Depth zones and fossil tracks*

130 The common sub-surface motion pattern among guineafowl steps allows depth-based  
 131 zones to be characterized by digit representation, digit III offset, and digit exit conformation,  
 132 (Fig. 1h, Table 2). In Zone 1 (Fig. 1h, 0-1 cm), the adducted claws exit in front of their entry,  
 133 often moving horizontally. In Zones 2 and 3, digit III offset is negative (Fig. 1h, 3-13 cm). All  
 134 three toes are tightly converged when passing back up through Zone 2, but exit separately in  
 135 Zone 3. The deepest zone can be further subdivided by the number of main toes represented: all  
 136 three (3a), only two (3b), or just digit III (3a).

137 Using guineafowl sub-surface kinematics as a reference, we are now able to confirm the  
 138 presence of comparable looping and depth zones in fossil penetrative tracks from Lower Jurassic  
 139 strata of the Connecticut Valley (Fig. 2). Single slabs exposing penetrative tracks on both  
 140 surfaces (Fig. 2b, c) support depth-based predictions of digit representation, anterior-posterior  
 141 digit III offset, and digit exit conformation. Such patterns are particularly well-displayed when  
 142 track volumes are split into multi-slabs. A five-slab specimen exposing track surfaces across  
 143 Zones 2 and 3 preserves not only evidence of looping, but also allows specific details of digit III  
 144 loop expansion and contraction to be distinguished (Fig. 2d).

145

Zone	digit representation	digit III offset	digit exit conformation
<b>1</b>	II - IV	exit in front	three converged
<b>2</b>	II - IV	exit behind	three converged
<b>3a</b>	II - IV	exit behind	three separate
<b>3b</b>	II + III or III + IV	exit behind	two separate
<b>3c</b>	III	exit behind	single

148

149 **Discussion**

150 *(a) Impact on track diversity and interpretation*

151           Documentation of sub-surface looping in guineafowl walking through a wide variety of  
152 substrates offers a new perspective on the tracks of extinct bipeds. If dinosaurs responded to  
153 deformable ground similarly, we expected that the claws of the three main toes would have  
154 likewise passed through most surfaces twice—once going down and once coming back up—in  
155 different locations. Treatments of the Early Jurassic fauna of the Connecticut Valley [37-38,49-  
156 51,56,63-64] do not recognize any evidence of withdrawal. Yet armed with an improved search  
157 image, we have identified distinctly separate entry and exit features in hundreds of fossil  
158 footprints (sampled in Fig 2). Once penetrative tracks are understood as slices through a  
159 disturbed volume of sediment, their true nature becomes apparent. Such surfaces do not represent  
160 anatomy per se, but rather the collapsed seams left behind by toes punching, slashing, scraping,  
161 and ascending into and out of each potential track horizon on their looping paths.

162           A shared kinematic response to deformable substrates does not, however, mean that  
163 movements were tightly stereotyped. X-ray imaging allows us to measure guineafowl inter-step  
164 variation directly (Fig. 1e, g). In extinct dinosaur tracks, such kinematic variation must be  
165 inferred from its morphological consequences. For example, Connecticut Valley tracks  
166 assignable to Zone 2 reveal a wide range of loop-related disparity (Fig. 2e). Some preserve toe  
167 withdrawal back up through the entry furrow of digit III (Zone 2, left), others near the confluence  
168 of the digital furrows (Zone 2, middle), and yet others at the very rear of the track (Zone 2,  
169 right). Workers have attributed such a diverse array of shapes to multiple taxonomic groups  
170 (lizards, thin-toed birds, reptiles of uncertain affinity, and vertebrates of unknown class [38,50]).  
171 Yet despite their distinctive forms and deviation from known dinosaurian pedal anatomies, we

172 propose that this diversity of penetrative tracks could all have been created by small theropods  
173 and/or ornithopods.

174

175 *(b) Foot function in birds and other dinosaurs*

176 Evidence of sub-surface looping in ~200 million-year-old fossils supports the hypothesis  
177 of functional continuity among tridactyl feet of birds and other bipedal dinosaurs when walking  
178 through deformable substrates. Although sub-surface looping has been previously reported in  
179 several dinosaur tracks [65-67], loops are ubiquitous and often of substantial magnitude in these  
180 Early Jurassic penetrative specimens. Our kinematic perspective offers a fresh viewpoint on  
181 depth-based track variation. Rather than being incomplete molds beneath the surface [38,68],  
182 substrate-modulated foot motion is intimately accountable for these disparate tracks. Perhaps the  
183 enduring success of the dinosaurian tridactyl foot design can be attributed, at least in part, to its  
184 ability to provide a stable base when spread, yet collapse to facilitate extraction from deformable  
185 substrates.

186

Figure 2. Exit features and depth zone attribution in Early Jurassic fossil tracks. (a) Digit tip impression identification on entry (small circles) and exit (large circle) on one surface of ACM-ICH 37/24. (b) A penetrated slab (ACM-ICH 39/8) from high in the volume reveals three elongate Zone 1 tracks on its upper surface and furrowed, Zone 2 tracks on its lower surface (mirrored). (c) A penetrated slab (ACM-ICH 31/50) from low in the volume reveals a scrape-like, Zone 3a track with separate exits on its upper surface; only digit III reached its lower, Zone 3c surface (mirrored). (d) A five-slab specimen (ACM-ICH 34/33) preserves the down and forward penetration of the foot, followed by its looping withdrawal. Note changes in track morphology with depth. Dashed line indicates the entry (thin) and exit (bold) paths of digit III. (e) Tracings of 19 Early Jurassic track surfaces displaying inter- and intra-zone diversity (ACM-ICH specimen numbers shown below). Exit features (black arrows) vary widely in location along the lengths of the tracks (see electronic supplementary material, figure S1 for specimen photos and entry/exit overlays). Scale bars equal 5 cm.
